Non-Technical Abstract

This paper analyses the effect of emigration from Poland around the time of EU accession on the Polish labour market. We develop a simple model that guides our empirical specification and provides a clear interpretation for our estimates. Focussing on the 1998–2007 period for Poland, we use a unique data set that contains information about household members who are currently living abroad, which allows us to develop region-specific emigration rates and estimate emigration's effect on wages using within-region variation. Our results show that emigration from Poland was largest for workers with intermediate-level skills and that it is wages for this skill group that increased most. We also show that emigration led to a slight increase in wages overall but that workers at the low end of the skill distribution made no gains and may actually have experienced slight wage decreases.

* We gratefully acknowledge financial support from the Rockwool Foundation, and we are grateful to Torben Tranaes for his support throughout the project and the many helpful discussions. We also thank Iga Magda for her invaluable help with the data and Orazio Attanasio, Bernt Bratsberg, David Card, Francesco Fasani, Bernd Fitzenberger, Giovanni Facchini, Albrecht Glitz, Florian Hoffmann, Thomas Lemieux, Ian Preston, Uta Schoenberg and participants at the CReAM–NORFACE Conference "Migration: Economic Change, Social Challenge", the 3rd Norface Migration Conference, the Fafo-Frisch Centre Workshop "Moving for work", and at seminars at the University of British Columbia, the University of Bologna and the Federico II University of Naples for their constructive comments. Dustmann acknowledges support from the Norface migration programme.

1. Introduction

Since the late 1990s, Poland has experienced a dramatic increase in emigration. Whereas in 1998, the share of emigrants in the overall population was about 0.50%, by only a decade later, it had increased to 2.3%.[1] Nevertheless, there is large regional variation in emigration rates, with a 2007 share of emigrants that ranges between 1% and 5.6% across Poland's 16 provinces (Table 2). This decade also saw a change in the composition of the emigration flow: emigrants became increasingly younger and were better educated than non-emigrants. These large increases in emigration, together with the variation in emigrant skill composition, are likely to have had a notable impact on the Polish labour market and, in particular, on the wages of those who stayed behind. It is this question that we address in this paper.

Specifically, we investigate the wage impact of emigration over a period of 10 years (1998–2007) when emigration from Poland was at its highest. Because our data set includes rare detailed information on emigrants and their education and age structure, it allows us to assign emigration rates to local labour markets and determine the emigration-induced changes in skill ratios within local labour markets. We use the variation in emigration rates within Poland's regions to identify the effects of emigration on the wages of non-emigrants.

Although our paper is related to the literature on the impact of migration on wages, rather than concentrating, as most studies do, on the wage impacts in the countries of destination,[2] it is part of only a small body of work that investigates the impact of emigration on the labour markets of sending countries. One reason such studies are scarce is the difficulty of obtaining

[1] See Table 1, based on the Polish Labour Force Survey.

[2] See, for instance, early work by Altonji and Card (1991), Angrist and Kugler (2003), Card (2001), Borjas (2003), Card and Lewis (2007), Dustmann, Fabbri, and Preston (2005), Jaeger (2007), and more recent papers by D'Amuri, Ottaviano, and Peri (2010), Dustmann, Frattini, and Preston (2012), Glitz (2012), Manacorda, Manning, and Wadsworth (2012), and Ottaviano and Peri (2012).

information on emigrants, a problem that Aydemir and Borjas (2007) and Mishra (2007) overcome by exploiting the fact that over 95% of emigrants from Mexico go to the U.S. After first measuring the size and composition of Mexican emigrants from U.S. censuses and wages in Mexico from Mexican censuses, these authors follow the identification strategy proposed by Borjas (2003) and correlate the wages of different skill groups in Mexico, defined in terms of age and education, to the proportion of emigrants from the same skill group in the U.S. Elsner (2010) uses a similar approach to study Lithuanian emigration, but he must rely on a number of simplifying assumptions to reconstruct the size of Lithuanian emigration based on Irish and UK data.[3]

We contribute to this literature by focussing on one large European country, Poland, which, although locked away behind the Iron Curtain for more than four decades, experienced a large amount of emigration from the late 1990s onwards. Rather than identifying emigrants based on census data and survey information from the *destination* countries, however (as did the aforementioned studies), we have access to detailed information (including age and education) on all emigrants measured in the source country, which allows precise computation of the regional distribution of emigrants in the country of origin. The availability in the data set of wage information for a sub-set of emigrants before they left the country also helps us to address the possible change in composition in the non-emigrant population because of selective out-migration.

[3] Other papers on the labour market effects of emigration include Hanson (2007), who compares changes in labour market outcomes between 1990 and 2000 in Mexican states with high and low historical level of migration (measured in the 1950s); Docquier, Ozden, and Peri (2011), who use an aggregate production function model to simulate the effect of immigration and emigration on wages and employment in OECD countries; and Elsner (2011), who uses a calibrated structural model of labour demand to simulate the effect of Lithuanian emigration on the wages of non-emigrant workers.

To better structure our empirical analysis and interpret our parameter estimates, we first present a model in which output is produced by combining capital with a CES labour composite. This model shows that wage effects are positive for skill groups in which out-migration falls above a weighted overall average along the skill distribution and that—if capital is insufficiently mobile in the short run—the overall wage effects can be expected to be positive. Our empirical results, based on estimations using within-region variation, suggest that, overall, emigration had a positive effect on the wages of those who did not emigrate. Across skill groups, it is those in the middle of the educational distribution particularly that experienced the largest gains from emigration. The effect on the highly educated is likewise positive, but smaller, while the effect on the wages of those with a low level of education is slightly negative, albeit mostly not significantly different from zero. This result is thus in line with emigration being more concentrated among individuals in the middle and upper parts of the educational distribution.

Because emigration from a particular region may be induced by negative wage shocks, we argue that such estimates are likely to constitute a lower bound on the effect of emigration on wages, and have therefore a meaningful interpretation. However, to account for the possibility of alternative directions of the selection bias, we develop an IV estimation strategy based on the detailed information we have available on the emigrants' destination countries. We combine these data with both the variations in economic conditions in the main destination countries (Ireland, Germany, the UK and the U.S.) and the large exchange rate fluctuations over this period and employ various strategies that exploit regional differences in destination preferences.

The structure of the paper is as follows. In Section 2 we give a brief overview of Polish emigration, describe the data, and outline the emigrants' main characteristics. In Section 3,

we explain the theoretical model while in section 4 we describe our empirical strategy. In Section 5, we present the OLS and IV results, and report several robustness checks; and in Section 6, we discuss the results and present our conclusions.

2. Background, data and descriptive evidence

2.1 Emigration from Poland

The first large-scale migrations from Poland took place toward the end of the nineteenth century after sluggish economic development and large population growth led many Poles to seek better opportunities in other countries. This trend intensified during the inter-war period: between 1919 and 1938, about one million people emigrated permanently to the U.S., France and Brazil (Zubrzycki 1953) and circulatory migration took place to Germany and Latvia. Although emigration slowed down after the great depression of the 1930s, in the period after WWII, emigration from Poland increased again, mainly for political motives. Between 1950 and 1992, more than two million Poles left the country (see Fassmann and Munz 1994), a large fraction moving to the United States.[4]

In the decade following the 1989 fall of the Berlin Wall, emigration from Poland was quite modest because of relatively favourable economic conditions in Poland. From about 1998 onwards, however, after a slowing in GDP growth and a decrease in employment, it began increasing steadily until it peaked in 2007. Figure 1 and Table 1 provide more detailed information about the overall recent emigration trends from Poland based on data from the Polish Labour Force Survey (PLFS), where observations are weighted using population weights (see below for details). As the figure shows, the stock of emigrants nearly quintupled

[4] As pointed out by Mostwin (1969), most Polish immigration to the U.S. after the Second World War was driven by political motives, and compared to earlier Polish immigrants, those who arrived post-WWII were better educated.

between 1998 and 2007, from just above 100,000 in 1998 to over 600,000 in 2007, but decreased slightly from 2007 to 2008 because of the global economic crisis, which severely affected the main destination countries.

In 2004, Poland became a member of the European Union, which gave its citizens the right to travel freely across all EU member states. In addition, the UK, Sweden and Ireland allowed Polish citizens full access to their labour markets, while the other EU countries took advantage of a seven-year transition arrangement under which Poles were refused the right to work. This constraint was not strictly imposed by all countries, however; for instance, Germany (on a case-by-case basis) gave many Poles access to its labour market, which led to annual increases in the number of emigrants of between 20% and 40% in the years after 2004 (see Kaczmarczyk and Okólski 2008 and Kaczmarczyk, Mioduszewska, and Zylicz 2009 for details on post-accession Polish emigration).

2.2 Data

The Polish Labour Force Survey (PLFS)

The main dataset for our analysis is the Polish Labour Force Survey (PLFS), a rotating quarterly panel of about 15,000 households, or 50,000 individuals per quarter, conducted by the Polish Central Statistical Office (GUS) in all Poland's 16 provinces[5] (*voivodeships*). This survey covers all individuals aged 15 and above who are living in the same household, and each household is interviewed four times: in two initial consecutive quarters and then again in two consecutive quarters after a gap of two quarters. Thus, the entire interview period spans 1.5 years. We focus on the data for the 1998–2007 period.

The PLFS provides information on demographic, personal and household characteristics of all the individuals interviewed, including age, education, current and past region of

[5] See the appendix for a more detailed description of the sample used.

residence, country of birth and number of children. It also collects detailed information on the economic activity of each household member during the week preceding the interview, including employment status, work arrangements, occupation, industry and monthly net wages. In addition, and most important for our analysis, it gathers detailed demographic information—age, education level, region of origin, relationship with other household members and country of present residence—for individuals who are part of the household but who have been residing abroad for more than three months. This information allows us to construct a comprehensive measure of out-migration. The survey also provides population weights for the resident population, which we employ throughout the analysis and also use to re-construct population weights for emigrants. We detail this procedure in Appendix A.2.

Other data sets

In addition to the PLFS, for some parts of the analysis, we draw on micro-data for Germany, the UK and the U.S. and aggregated data for Ireland (the four main countries of destination for Polish emigrants). In particular, we use these data to cross-check the validity of the emigration measures in the PLFS (see below) and to construct our instrumental variables (see Section 4.3), which are based on wage growth in the destination countries.

Information for Germany comes from IAB Employment History Data, a data set of administrative social security records available for 1975–2007. These data encompass all individuals covered by the social security system, which is about 80% of the German workforce, including all workers who are subject to social security contributions (excluding the self-employed and public employees). Because the database gives no information on country of birth, however, immigrants in this data set can only be identified based on their nationality. For the UK, we rely on the UK Labour Force Survey, a quarterly rotating panel survey available in its current format since 1992, which contains rich demographic and labour

market information, including gross wages, country of birth and years since migration. The U.S. data come from the IPUMS–CPS (Integrated Public Use Microdata Series of the March Current Population Survey), an integrated data set covering 48 years (1962–2009) of the March Current Population Survey (CPS). The CPS is a monthly household survey that gathers information on labour market status and demographics, including country of birth and years since migration. As neither the Irish Labour Force Survey nor on any other Irish micro-data set contain information on wages, we use aggregate wage information for Ireland provided by the Central Statistical Office, which reports weekly earnings by industrial sector, gender and type of employee. These data are based on the Earnings Hours and Employment Costs Survey (EHECS), a quarterly survey that covers all sectors of the economy other than Agriculture, Forestry and Fishing (NACE 5–96) using a sample of 7,500 enterprises that report information on the number of employees, hours, earnings and bonuses in that quarter.

2.3 Sample and Variables Construction

We use the PLFS data for 1998–2007 to construct the two key variables for our analysis: (i) emigration rates, by region and time period, and (ii) non-emigrant wages, by region, time period and educational group. We restrict our analysis to the age group between 15 and 65 years.

Emigration rates

One strength of the PLFS is that it reports information on household members who are emigrants. Specifically, when a household member is not present, another member of the household is asked about the person's whereabouts. If the individual emigrated abroad more than three months earlier,[6] detailed information on age, education, country of emigration and

[6] Individuals abroad for less than three months are not recorded as emigrants and cannot be separately identified in the data.

the individual's role in the household is collected in a separate questionnaire. This information, from which we construct our emigration rates, allows direct measurement of emigrant's individual characteristics, a major advantage over other studies that rely on destination country information to characterise emigrants. As we show in Appendix Table A1, our sample comprises on average of about 112 emigrants per region in every year, corresponding to about 10,000 individuals. In 857 cases, we observe individuals who were originally in the country but emigrated over the sampling period. For this sub-sample of individuals, we have a full set of information, not only standard demographics but also their wage and occupation in Poland before emigration. We use this information in Section 4.1 to analyse selection patterns among emigrants based on comparison of their residual wages with those of non-emigrants.

One drawback of computing emigration rates based on these data, however, is that such construction omits emigrants who lived in single households, as well as households in which everybody emigrates at the same time. Although theoretically, these omissions could potentially lead to under-counting, we do not anticipate they will pose a serious problem statistically.[7] First, the percentage of people actually living in single households in Poland is relatively small—between 8% and 9% on average (in contrast to about 18% in the UK in 2007), has remained fairly constant over the years, and is similar across regions. Single households are also far more frequent among the elderly: over 15% for the 50–64 age group versus about 8% for the 40–50 age group, and less than 7% for the 25–40 age group, which accounts for about half of all emigrants. Additionally, as reported in Section 5.1, we also perform robustness checks in which we re-construct the share of emigrants in the regional population by assuming that within groups defined by year, region, age and education, the

[7] In section 5.3 we present an interpretation of our regression results that is robust to systematic undercounting of emigrants.

share of single households in the emigrant population corresponds to the observed share of single households in the non-emigrant population (see Appendix A.5 for details). Finally, recent Polish emigration does not seem to be characterised by large family migration: for instance, Drinkwater et al. (2010) document that only about 6% of post-EU accession immigrants to the UK (of which Poles constitute the vast majority) brought dependants with them.

In any case, to directly assess the reliability of emigration data computed on the basis of the PLFS, we compare the destination-country data on trends in immigrant inflows into each country with PLFS data on trends in emigration to that particular country. We focus on the three main destination countries for Polish emigrants—Germany, the UK and the U.S.—which alone account for over 55% of all Polish immigration over the years considered**.** In Figure 2, we plot the evolution of the stock of Polish immigrants in these three countries as estimated from German, UK and U.S. micro-data (solid line) and from PLFS data (scattered line).[8] The estimates from these independent data sets are reassuringly similar, showing very similar trends across data sources. We also compute the 95% confidence interval for the difference in the two data series. For Germany, this difference is only statistically significant for the first three years (note that estimates are very precise, due to the large sample size of the German administrative data); for the UK, the difference is statistically significant only in 2007. The differences between the CPS and PLFS estimates for Polish immigrants are never statistically significant. Overall, therefore, these figures suggest that the emigration data we are using are quite accurate.

[8] We use the IABS, UK LFS and CPS data for Germany, the UK and the U.S., respectively. See Section 2.2 for details on these datasets. Because the UK LFS and CPS contain information on years since migration, we can in this case focus on recent emigrants, so in the figure, we plot the number of Poles who have been in the UK or the U.S. for less than two years. For the U.S. data, however, the measurement of Polish immigrants is noisy because of small sample sizes, so in the figure, we smooth the graph using a 3-year moving average.

The share of emigrants in the total working-age Polish population showed a dramatic increase between 1998 and 2007, from 0.50% to 2.29%, respectively.[9] At the same time, as illustrated in Table 2, there was substantial variation in emigration rates across the different regions and into the different destination countries. For some regions, the share of emigrants over the working age population increased more than tenfold between 1998 and 2007 (Lower Silesian), while for other regions it increased by less than 80% (e.g., Podlaskie). The 2007 share of emigrants ranges between 0.9% (Masovian) and almost 6% (Subcarpathian). As the table also shows, the destination countries have changed over the period. Whereas Germany was the main destination in 1997, absorbing about 27% of the Polish emigrant population, the largest destination country in 2007 was the UK (with 31% of all emigrants). Nevertheless, there is again some substantial variation across regions in the destinations chosen by emigrants.

Wages

The wage measure available in the PLFS is monthly net wages; that is, gross wages after deduction of income taxes and social security taxes. For the construction of our wage variable (which we compute by region/year), we pool all quarters within a year, restrict the sample to the working-age population (15–65) and drop the top and bottom wage percentile to eliminate outliers. We also eliminate all individuals who changed their migration status during the survey period so that regional mean wages within a calendar year are always computed for the non-emigrant population only, which minimises the changes in wages resulting from changes in sample composition. Over the period considered, real net wages increased on average by 1.4% per year.

[9] The emigration share is computed as the number of emigrants at time *t* over the working age population (emigrants + residents) in the same year *t*.

The tax system in Poland is progressive and the tax schedule, although it varies over time, is constant across regions. Therefore, based on information about the taxation rules and the information available on each household (see Appendix A.3 for details), we compute gross wages and then re-estimate our model to check the robustness of our results. Further, the response rate to the wage question in the PLFS decreases over our observation window, with non-response being higher among the highly educated. Hence, to check whether this decrease affects our results, we correct wages by imputing them for those who report being employed but do not report their salary (see Appendix A.4 for the procedure used).

2.4 Descriptive Evidence

Emigrants and non-emigrants

How do emigrants differ from non-emigrants? In Table 3, we report the average characteristics of emigrants and non-emigrants for the years 1998 and 2007. The figures in the table show that emigrants in both years are substantially younger than non-emigrants, with the average age for emigrants decreasing by about 2 years between 1998 and 2007. When education level is defined as either low, intermediate or high based on individual qualifications, emigrants are also far better educated. "Low education" refers to individuals with at most a lower secondary education, or up to 8 years of schooling; "intermediate education" refers to those with a secondary education, or between 9 and 13 years of schooling, and "high education" refers to individuals with post-secondary or tertiary education, or more than 13 years of schooling.[10] For both 1998 and 2007, the fraction of individuals with a low education is lower in the population of emigrants, while the fraction of those with an intermediate education is higher. The overall share of individuals with a low

[10] See Appendix A1 for a detailed explanation of the original classification in the Polish LFS.

education decreased substantially between 1998 and 2007 for both emigrants and non-emigrants, with the drop being even larger for emigrants. These figures suggest that emigrants are over-represented among the intermediate- and high-education groups but under-represented in the low-education group.

Are these numbers similar for the different regions and across time periods? We answer this question graphically in Figure 3, which (for all years and all regions) plots the share of each education group in the emigrant population against the share of each education group in the overall population. If the skill composition of the emigrant population were identical to that of the overall population, then all dots would lie on the 45 degree line. As the figure clearly shows, however, such is not the case: for most region-year pairs, the share of those in the intermediate-education group—and to a lesser extent, those in the high-education group—is higher among emigrants than among the overall population. In contrast, the share of individuals with a low education is clearly lower among emigrants than in the overall population. These numbers suggest that emigration led to a decrease in the share of the population with intermediate and high education but to a relative increase in the share of the less educated. We discuss the expected consequences of this fact on non-emigrant wages in the next sub-section.

Destination countries

How, then, are emigrants to the different destination countries selected along the education distribution? In the first column of Table 4, we report the share of Polish emigrants living in Germany, Ireland,[11] the UK and the U.S., as well as the overall number living in any EU27[12] country, for the years 1998 and 2007. The table reports both figures for all Polish

[11] According to the Polish LFS, there were no emigrants to Ireland in 1998.

[12] In Appendix Table A2, we break down the percentage of emigrants residing in each of the European countries.

emigrants, and for those who emigrated within the last year (recent emigrants). In 1998, almost one third of all Polish emigrants lived in the U.S., just under 30% in Germany, and only 5% in the UK. The new flows of emigrants, however, were mostly directed toward Germany (36%), and to a lesser extent the U.S. (15%), with only 6% of new emigrants going to the UK and no emigration to Ireland. By 2007, in contrast, the situation was reversed: one third of Polish emigrants were now living in the UK, 18% in Germany, 12% in Ireland and only 6% in the U.S. This shift reflects a sharp change in the destination of emigration flows: in 2007, 37% of new Polish emigrants chose the UK as a destination, 12% chose Ireland, 16% chose Germany and only 3% moved to the U.S. In that same year, 88% of the entire population of new Polish emigrants moved to EU countries, which by 2007 accounted for 84% of all Polish emigrants, up from 55% in 1998.

The destination countries do, however, differ greatly in the composition of their Polish immigrant population. In columns (2–4) of Table 4, we report the distribution of immigrants across education groups in each destination country, and in column (5), we show the average age of emigrants in the different countries. Emigrants to Germany and the U.S. are older and less educated, while emigrants to the UK and Ireland are far younger, with a higher share of those with intermediate or high education. Although the average age of emigrants in the U.S. has remained stable over the years, emigrants to Germany became older, especially compared to the average age of the total emigrant population.

3. Theoretical Framework

Drawing on work by Dustmann, Frattini and Preston (2012), we next develop a model that helps us to interpret the parameters estimated below. Assume that the number of output types (output being denoted by y) is equal to one, and that there are multiple labour types,

i=1,…,L. We normalise the price of *y* to 1. We then adopt a nested CES production function, which produces output *y* by combining a labour composite *H* with capital *K*:

$$y = \left[\gamma H^{s} + (1-\gamma)K^{s}\right]^{1/s} \tag{1}$$

where *H* is a CES aggregate of the different labour types l_i, $H = \left[\sum_i \alpha_i l_i^{\sigma}\right]^{1/\sigma}$, and α_i determines the productivity of the *i*th type of labour. Accordingly, $\sigma \leq 1$ determines the elasticity of substitution between labour types, γ determines the relative productivity of labour and capital, and $s \leq 1$ determines the elasticity of substitution between capital and labour.

We assume that emigrant and non-emigrant labour of the same type are both perfect substitutes and equally productive, so that non-emigrant labour of type *i*, l_i, is the difference between labour before migration l_i^0 and emigrant labour, l_i^1: $l_i = l_i^0 - l_i^1$. For the markets for each labour type to clear, $l_i = n_i$ for all *i*, where n_i is the supply of labour of the *i*th type. The labour supply n_i is then the difference between labour supply in the particular skill group before emigration n_i^0 and emigrants n_i^1, so that $n_i = n_i^0 - n_i^1$. It follows that $n_i = N(\pi_i^0 - \pi_i^1 m)$, where $N = \sum_i n_i^0$ is total (pre-migration) labour supply, $\pi_i^0 = n_i^0 / N$ is the fraction of total labour supply of the *i*th type, $\pi_i^1 = n_i^1 / \sum_j n_j^1$ is the fraction of emigrant labour of the *i*th type and $m = \sum_j n_j^1 / N$ is the ratio of emigrants to the total (pre-migration) labour force. The first-order conditions for profit-maximising input choice imply that the real wage of the *i*th type of labour, w_i, equals its marginal product. Similarly, the price of capital, ρ, equals the marginal product of capital. Deriving the first-order condition and taking logs results in an expression for the equilibrium real wages of all labour types (and equivalently for capital *K*):

$$\ln w_i = \ln \frac{\partial y}{\partial l_i} =$$

$$= \ln \gamma \alpha_i + (\sigma - 1)\ln(\pi_i^0 - \pi_i^1 m) + (1-\sigma)\ln\left(\frac{H}{N}\right) + \left(\frac{1}{s} - 1\right)\ln\left[\gamma + (1-\gamma)\left(\frac{K}{H}\right)^s\right] \quad (2)$$

where $\ln\left(\frac{H}{N}\right) = \frac{1}{\sigma}\ln\left(\sum_j \alpha_j (\pi_j^0 - \pi_j^1 m)^\sigma\right)$

To derive the effect of emigration on the mean wage and on the wages for the different skill groups of non-emigrants, we suppose an elasticity of supply of capital given by $\theta = \frac{\partial \ln K}{\partial \ln \rho}$. We can then show the equilibrium change in non-emigrants' log wages in reaction to changes in the ratio of emigrants to total population as follows (see Dustmann et al. (2012) for details):

$$\left.\frac{d \ln w_i}{dm}\right|_{m=0} = (1-\sigma)\left(\frac{\pi_i^1}{\pi_i^0} - \phi \sum \omega_j \frac{\pi_j^1}{\pi_j^0}\right) \quad (3)$$

where ω_i is the contribution of the *i*th type to the labour aggregate H^σ, with $\sum_i \omega_i = 1$; ψ is the contribution of labour to the overall CES aggregate y^s; and ϕ is a parameter that depends on capital mobility θ, capital-labour substitutability s and the labour share ψ. It should be noted that (3) implies that the pattern of emigration's effects on each skill-specific non-emigrant wage depends upon the relative density of emigrants and pre-migration population $\frac{\pi_i^1}{\pi_i^0}$ at that skill type.

Consider first the case of $\phi = 1$, which arises if capital is perfectly mobile ($\theta = \infty$) (assuming that capital and labour are not perfectly substitutable, $s \neq 1$, and the capital share is

not equal to zero, $\psi \neq 1$).[13] Since $\sum_i \omega_i = 1$, the rightmost expression in parentheses in (3) is the difference for that skill type between the relative density of emigrants and total labour supply and a weighted average of these relative densities across the skill distribution. The wage of any skill type is increased by emigration if and only if the intensity of emigration at that point exceeds an appropriately weighted average of emigration intensity across all skill types. If the distribution of skill types in the emigrant outflow exactly matches that in the total labour force (before emigration), then $\pi_i^0 = \pi_i^1$ for all *i* and the effect on wages everywhere is zero.

If capital is used, that is imperfectly mobile and imperfectly substitutable with labour, then $\phi < 1$. In this case, even emigration that matches the pre-migration labour force in composition will result in wage gains because $\pi_i^1 / \pi_i^0 > \phi \sum \omega_j (\pi_j^1 / \pi_j^0)$. The pattern of wage effects along the distribution will be driven in just the same way by the relative density of emigrants and pre-migration population $\frac{\pi_i^1}{\pi_i^0}$.

The effect of emigration on *mean* wages of those who do not emigrate $\sum_i w_i \pi_i^0$ is:

$$\left. \frac{d \ln w_i}{dm} \right|_{m=0} = (1-\sigma)(1-\phi)\overline{w}^0 \sum \omega_i \frac{\pi_i^1}{\pi_i^0} \geq 0 \qquad (4)$$

where $\overline{w}^0$ is the mean wage before emigration. If capital is perfectly mobile so that $\phi = 1$, then this effect is zero. That does not, of course, mean that in this case wage changes are zero

[13] This result follows from $\phi = 1 + \frac{(1-s)(1-\psi)}{1+(1-s)\psi\theta} \frac{1}{(\sigma - 1)}$, which is equal to 1 if capital is perfectly mobile ($\theta = \infty$).

for all skill types: as explained above, wages increase at any point in the distribution at which $\frac{\pi_i^1}{\pi_i^0}$ exceeds the weighted average $\sum \omega_i \frac{\pi_i^1}{\pi_i^0}$.

4. Empirical Implementation

In our empirical implementation, we define skill groups based on education level. Taking a Taylor approximation of (2) around $m = 0$ using (3), we obtain an estimable equation:

$$\ln w_{irt} = a_{ir} + b_{it} + c_i X_{rt} + \beta_i m_{rt} + \varepsilon_{irt} \quad (5)$$

where $\ln w_{irt}$ are log mean wages of the non-emigrant population in skill group *i*, period *t* and region *r*; a_{ir} and b_{it} are region and time dummies, collecting terms that vary across regions and over time; and X_{rt} controls for changes in the age and skill composition of the overall labour force. The parameter β_i corresponds to the term $(\sigma - 1)[\pi_i^1 / \pi_i^0 - \phi \sum \omega_j (\pi_j^1 / \pi_j^0)]$ given above and measures the effect of emigration on the wages of skill groups *i*. Our model thus provides a clear-cut prediction for our parameter estimates: when we regress wages for a particular skill group on the fraction of emigrants to the overall workforce, m_{rt}, the sign of this parameter estimate is positive (as $\sigma < 1$) if emigrants are more densely represented in that skill group than the total population (emigrants and residents). Additionally, the larger this estimate, the smaller the short-run supply elasticity of capital. Finally, it follows from (4) that emigration will only have positive effect on average wages of those who stay behind if the elasticity of capital supply is smaller than 1 so that capital is not perfectly mobile (at least in the short term).

We measure m_{rt} as the ratio of emigrants in a particular region at a particular point in time to the total regional population before emigration: m_{rt} =$Emigrants_{rt}$/($Emigrants_{rt}$ + $Residents_{rt}$). The vector X_{rt} collects additional control variables about the resident regional

population, which include average regional age, the ratios of the number of individuals with high and intermediate education to the number of individuals with low education in the region, and the logarithm of the resident regional population. We detail these variables in Table 5.

We estimate (5) by conditioning on region-specific fixed effects, thereby effectively identifying the impact of emigration on wages through variation in the emigration share (m_{rt}) within regions and over time, controlling also for year fixed effects. For regions, we use all 16 Polish *voivodeships* and for time, the years 1998–2007 (see Table 2). The resulting data include 160 observations for each skill group.

4.1 Internal Migration and Composition Effects

Internal migration

If regions that experience high international emigration are also receiving internal immigrants, it could offset the effects of international emigration and lead to an under-estimation of the effect of emigration on wages. If instead the same regions that experience high international emigration also experience emigration to other Polish regions, it could lead to over-estimation of the effect of international emigration on regional wages (see Borjas, Freeman, and Katz 1996, 1997 for a related discussion). Because the PLFS reports since 2001 information on region of residence one year before the interview, we can use these data to check the degree of internal migration across the different Polish regions and the nature of its association with international migration.[14]

Overall, internal mobility in Poland across regions is low and decreasing over time; for instance, in 2001, 0.24% of the population reported living in a different region than in the

[14] Note also that the regions we use are relatively large, so that internal migrations that may occur may take place within these regions.

previous year, and this share decreased to 0.12% in 2007. To check whether these internal movements are correlated with international emigration, we regress the share of internal migrants in the total regional population on the share of international emigrants, controlling for region fixed effects and time dummies. The resulting estimate is small, negative and not statistically significant (we estimate a coefficient of -0.041 with a standard error of 0.027). Likewise, regressing the share of internal migrants in each region and year on the share of international migrants by skill group (controlling for year and regional dummies) produces estimates that are not significantly different from zero.[15]

We also run further regressions along the lines of Card and DiNardo (2000) to check whether emigration does indeed affect the proportion of the population in different skill groups but find no evidence that the internal mobility decisions of individuals in a skill group are affected by the international emigration of individuals in the same skill group (results are available on request).

Composition effects

A further source of concern is the possibility that emigrants are not a random sample of the regional population within each skill group *i*.[16] If migrants within skill group *i* are positively (negatively) selected, then average wages for Polish residents in skill group *i* could decrease (increase) after emigration purely as a result of a composition effect. To check for such selection, we compare the log-wage residuals of non-emigrants versus emigrants using

[15] Our estimated coefficients (standard errors) are -0.023 (0.028) for the low-education group, -0.021 (0.027) for the intermediate-education group, and 0.006 (0.06) for the high-education group.

[16] See e.g. Chiquiar and Hanson (2005) and Fernández-Huertas Moraga (2010) for recent studies on emigrants' self-selection and Hatton and Williamson (2006) for an historical overview.

the sample of 857 emigrants for which we have pre-emigration wage data (see Section 2.3).[17] The overall mean difference in residual wages between emigrants and non-emigrants is not significantly different from zero, and neither are the mean differences by education group.

4.2 Non-Random Emigration and OLS as Lower Bound Estimates

A further potential problem with specification (5) is that emigration choices may not be random. That is, although region fixed effects account for permanent regional differences—and therefore also for the fact that, for instance, emigration may be higher from rural or traditionally less wealthy regions—even after they are controlled for, region-specific shocks affecting the wages of skill group i in year t (ε_{irt}) could be correlated with regional emigration flows in the same year. If so, our OLS estimates would be biased.

If, as seems plausible, emigration is higher from regions that experience negative wage shocks, then this association may induce a spurious negative correlation between emigration and wage growth that would lead to a negative bias in the OLS estimate of the effect of emigration on mean wages. Hence, the OLS estimator provides a lower bound for the actual effect of emigration on mean wages. Additionally, the OLS estimates are also a lower bound for the effect of emigration on the wages of each skill group *i*, as long as skill-specific shocks are positively correlated within regions in every year. We test this assumption by running separate pair-wise regressions of regional wage growth rates for each skill group on the wage growth of all other skill groups, controlling for year dummies. In all cases, we find that the growth rates of wages for all skill groups are positively correlated within regions, although

[17] We compute residuals from a weighted log-wage regression on education (3 categories), age, age squared, occupation dummies for each 1-digit ISCO08 occupation group, region and year dummies.

the estimated coefficients are not significant for the correlation between the wages of the individuals in the low- and high-education groups.[18]

4.3 Instrumental Variables Estimation

As we explain above, under plausible assumptions we can interpret our OLS estimates on the effect of emigration on the wages of non-emigrants as *lower* bounds. However, the bias of the OLS estimates could go in the opposite direction if other unobservable factors are simultaneously affecting positively emigration flows and wage growth. Although we do not believe that such a scenario is very plausible, we nevertheless use an IV strategy to identify the causal effect of emigration on wages. This requires an instrument, or set of instruments, that is correlated with m_{rt}, the ratio of emigrants over the total population in region *r* at time *t*, but uncorrelated with ε_{irt}, the economic shock hitting region *r* at time *t*, conditional on time-region dummies and the set of individual characteristics included. Because Polish emigration before 1997 was so low, we cannot construct an instrument similar to that used in most of the literature which identifies the effect of immigration on native outcomes based on spatial variation; that is, an IV strategy based on the idea that past location choices of immigrants are not correlated with current region-specific shocks, but are good predictors of current immigrants' location decisions (see, e.g., Altonji and Card 1991; Card 2001; Cortes 2008; Frattini 2010; Bianchi, Buonanno, and Pinotti 2011; Dustmann et al. 2012; Lewis 2011). Instead, we adopt an IV strategy based on economic shocks to destination countries, shocks that are likely to influence emigration (testable) while being uncorrelated with the shocks to a particular Polish region (our identifying assumption). We allow the effect of these shocks on

[18] We estimate a coefficient (standard error) of 0.898 (0.257) for the regression of low-skilled wages on intermediate-skilled wages; 0.196 (0.145) for the regression of low-skilled wages on high-skilled wages; 0.303 (0.148) for the regression of high-skilled wages on intermediate-skilled wages.

the probability of migration to differ across regions through regional heterogeneity in migration costs to each potential destination country. One reason why migration costs to each country *c* may differ across regions are differences in historical ties with the destination country *c* (e.g. regions close to the German borders have stronger links with Germany, see e.g. Kraetke, 1996 and 1999) or regional variation in the relative size of the existing stock of emigrants in each destination country (see e.g. Munshi, 2003, McKenzie and Rapoport, 2007 and Pedersen, et al. 2008 for the importance of network effects on migration decisions). Furthermore, differences in geographical proximity, in the share of each region's population who speaks the host country's language, or in the distance from airports with international flights are all factors that may lead to cross-region heterogeneity in the pull effect of shocks from destination countries.

To implement our strategy, we consider the four countries to which the majority of Polish emigrants migrated over the period under consideration, Germany, Ireland, the UK and the U.S.. On average, about 65% of all emigrants settled in these countries between 1998 and 2007. For each of these countries, we define a variable Z_t^c that captures the attractiveness of the respective destination country *c* for potential migrants. Each variable Z_t^c is expected to be correlated with the inflow of immigrants into country *c* but should not be correlated with any shock specific to a particular Polish region. Note that any possible correlations of Z_t^c with economic shocks that are common to all Polish regions are fully captured by the time dummies. Our exclusion restriction is that shocks to the destination countries have no region-specific consequences for Poland apart from changing relative gains from migration.

In our preferred specification, we define Z_t^c as the annual growth rate of real wages at those parts of the wage distribution or in those sectors where Polish immigrants are most

likely to be employed in each destination country *c*,[19] expressed in Polish Zloty (see Appendix B for details). We then allow the effect of each Z_t^c to differ across different Polish regions *r* by interacting Z_t^c with regional dummies R_r and define $Z_{rt}^c = Z_t^c \times R_r$. Finally, we account for the change in the relative role of economic shocks in different countries on migration decisions caused by the 2004 EU enlargement. We define two dummy variables EU_1 and EU_2 that identify the period in which Poland was not an EU member (up to and including 2003) and the years after Poland joined the EU (2004 onwards), respectively. We then interact Z_{rt}^c with EU_p (p = 1,2) and define $Z_{rpt}^c = Z_{rt}^c \times EU_p$.

This results in a vector **Z** of 120 instruments (i.e., 4 destination countries x 16 regions x 2 time periods = 128, of which 8, one region for each country for the years before and after 2004, must be set to zero for normalisation). Our first-stage regression is thus

$$m_{rt} = \sum_{c\in(DE,IE,UK,US)} \sum_{r=1}^{R} \sum_{p=1}^{2} b_{crp} Z_{rpt}^c + X_{rt} g + \sum_{r=1}^{R} d_r R_r + \sum_{t=1}^{T} f_t \tau_t + v_{rt} \qquad (6)$$

Each coefficient b_{crp} captures the effect that a shock to destination country *c* has on the emigration rate in region *r* before (p = 1) or after (p = 2) Poland joined the EU, net of time-invariant regional characteristics R_r, nationwide time-variant shocks τ_t, and other exogenous factors X_{rt}. We expect shocks to country *c* to have a higher impact on emigration (i.e., b_{crp} to be larger) in regions in which a larger fraction of total emigration is directed to that destination country. In Figures 4 and 5, we plot the estimated coefficients b_{crp} versus the fraction of the mean number of emigrants over the mean population in period *p* from each region *r* in each destination country *c* for the years before and after 2004, respectively. As the

[19] We use the growth rate of average wages below the 40th percentile for Germany, the UK and the U.S., and the growth rate of wages in the construction and manufacturing sectors for Ireland.

figures show, the coefficients that weigh shocks in each country to different regions are positively correlated with the regional fraction of emigrants to that destination country except in the case of the U.S. and Ireland[20] for the years before 2004. This correlation reassures us that our coefficients b_{crp} are picking up actual effects of destination country shocks on regional emigration.

Alternative definition of instruments

One concern with the IV strategy described above is that the number of instruments (120) is very high, and close to the number of observations (160). In this case the IV estimate might be biased toward the OLS estimate. For this reason, we check the robustness of our IV estimates to alternative definitions of instruments where we use different strategies to reduce the dimensionality. First, we select only the variables that are individually statistically significant. We estimate (6) and select only those variables for which the coefficient is statistically significant at the 1 percent level. This procedure reduces the number of instruments to 44. Second, we use two different model selection algorithms: backward elimination and forward selection. In the backward-elimination model we start from the full set of instruments, and drop at every step the variable that is least significant, provided that the *p*-value of a *t*-test for the null of a zero coefficient is higher than 10%. The procedure stops when estimated coefficients for all the included variables are statistically significant at 10%. This algorithm leads to selecting 77 instruments. Similarly, in the forward selection model we start from the model estimated with just a constant term, and then add, alternatively, each of the other candidate instruments. We then select the variable with the highest statistical significance, add it to the model, and then iterate the procedure, selecting at

[20] It should be noted, however, that the share of Polish emigrants in Ireland before 2004 was extremely low and migration to the U.S. also declined sharply over this period.

each step one additional variable until no additional variable is statistically significant at 10%. This procedure reduces the number of instruments to 23.

Our third strategy is to model the differential effects of destination country shocks on Polish regions with pre-assigned continuous regional weights (ω_r^c) and to use $\omega_r^c \times Z_t^c \times EU_p$ as instruments, rather than relying on estimated region-country pair specific weights. Doing so reduces the dimensionality of our instruments vector **Z** to 8. We use two alternative weights. First, we use the inverse of the distance between each region's capital and the capital of the destination country *c*. The assumption in this case is that migration costs increase with distance, so the shocks to destination countries should have a higher pull effect on regions that are closer. Second, because a number of papers have illustrated the importance of migration networks on migration decisions (see e.g., Bartel 1989; Munshi 2003), we expect shocks from country *c* to have a stronger pull effect on emigration from regions in which a higher share of individuals had previously emigrated to that specific country. As we have no reliable data on historical regional emigration to different destination countries, we cannot measure the historical strength of regional migration networks. We can, however, measure the strength of regional migration networks to destination country *c* using the mean share of emigrants from region *r* to country *c* over the 1998–2007 period. In constructing this variable, we reduce possible feedback by excluding, in every year *t*, the share of emigrants in year *t-1*, *t* and *t+1*, meaning that in practice, for every year t_0, we define weights $\omega_{rt_0}^c$ *:*

$$\omega_{rt_0}^c = \frac{1}{N_{t_0}} \sum\nolimits_{t<t_0-1, t>t_0+1} emigrants_{rt}^c / emigrants_{rt}$$

where N_{t_0} is the number of years over which the mean is computed in year t_0.

Finally, we check the robustness of our results to the use of alternative variables as "pull factors" Z_t^c. As explained above, in our baseline results, we define Z_t^c as the growth rate of average wages below the 40th percentile, expressed in zloty, in destination country *c*. Here, we experiment with one alternative: the deviation of the national per capita GDP growth in year *t* for country *c*, GDP_t^c, from the OECD mean GDP growth,[21] GDP_t^{OECD} (see McKenzie, Theoharides, and Yang (2010) for evidence on the role of the GDP growth in destination countries on migration choices). Because the resulting variable $\Delta gdp_t^c = GDP_t^c - GDP_t^{OECD}$ captures the relative economic performance of country *c* relative to other OECD countries, we expect it to measure the nation's relative attractiveness for potential migrants.

5. Results

5.1 OLS results

In Table 6, we report OLS estimates of β in expression (5) for average wages (row 1) and for the wages of the different education groups (rows 2 to 4). Panel A reports our baseline results, while panels B-D report different robustness checks. Column (1) reports the results from a specification that controls only for regional fixed effects and year dummies, while column (2) reports results when controls are added in for the size of the regional population, the average age in the region, and the educational and gender composition (see Section 4 for more details). All regressions refer to the years between 1998 and 2007. In panel A, we use net wages, as reported in the survey (see Section 2.3). The estimates in row 1 show that emigration is associated with a higher growth of regional average wages: the estimated coefficient ranges between 0.97 in column (1) and 1 in column (2) and is statistically

[21] In both cases, the GDP is in U.S. constant dollars. Source: *OECD Statistical Extracts* (http://stats.oecd.org/Index.aspx).

significant in both cases at the 10% level. Because the variation used for estimation is the change in the stock of emigrants between consecutive years, these are short-run estimates. As pointed out in our theoretical discussion in Section 3, a positive overall effect of emigration is compatible with the elasticity of capital supply not being infinite, at least in the short run. In terms of magnitude, the estimates in columns (2) imply that an increase of one percentage point in the ratio of emigrants to the total population led to a 1% increase in average real wages.[22] Over the period considered, emigration from Poland increased on average by 0.19 percentage points per year and real wages increased by about 1.7% per year. These estimates therefore suggest that emigration may have contributed almost 11% to overall wage growth.

In rows 2–4 of Table 6, we report the results for the three different education groups. The figures in Table 3 suggest that emigration was mainly concentrated in the middle part of the educational distribution and far less at the bottom. In particular, the relative intensity of emigration (the ratio $\frac{\pi_i^1}{\pi_i^0}$ in the notation of our model in section 3) was between 0.42 and 0.31 for the low educated, between 1.22 and 1.14 for those with intermediate-level education, and between 1.2 and 1.05 for the high educated. According to the model developed in Section 3, the effect of emigration should thus be felt most by those with intermediate education because this group experiences the largest (negative) relative supply shock. The results in rows 2-4 of Table 6 are in line with these predictions, suggesting that emigration led to an increase in wages for workers with an intermediate or high level of education but possibly depressed wages for those with low education. The estimates for the low-education group are however not significantly different from zero.

[22] See also section 5.3 for an interpretation of the results in terms of elasticity and a comparison with results from other studies.

Overall, these results conform remarkably with the predictions of the simple model outlined in Section 3, with larger gains for workers in the skill categories exposed to a larger negative supply shock. They also indicate that emigration helped overall wage growth in Poland over the period under consideration, although it may have reduced returns to capital.

The next three panels provide additional results and robustness checks that address the data limitations outlined in Section 2.3. In panel B, we use gross wages as the dependent variable, constructed from the information on net wages and individual characteristics (see Appendix A.3 for details). The results are very similar to those reported in panel A with the estimates for the low-education group being slightly larger but not significantly different from zero. In panel C, we account for non-response to the PLFS wage question by imputing (net) wages for those individuals for whom wage information is missing (see Appendix A.4 for details). Again, the estimates are in line with our baseline results, although the estimated coefficients are slightly smaller. In panel D, we report the results after correction of the emigration share measure for possible under-counting because of the single emigrant households not captured in our data. We assume that single households are as frequent among emigrants as among non-emigrants within the same age-education group in every region and year, and re-scale the number of emigrants accordingly (see Appendix A.5 for details). This re-scaling slightly reduces the size of all estimated coefficients relative to the baseline, with the exception of those in the low-education group, which are now slightly larger.

5.2 IV Results

We note above that the estimates presented in section 5.1 may be biased, due to the possibility of selective out-migration from areas that experienced a negative wage shock, but can reasonably be interpreted as lower bounds of the causal effect. In this section, we adopt the IV strategy described in Section 4.3 to try and remove the potential OLS bias.

In panel A of Table 7 we report our IV estimates when we use as instruments wage growth (in Polish purchasing power) in each destination country, interacted with regional dummies and dummies for the period before and after EU accession (see Section 4.3). As before, column (1) shows results from a specification where the only additional variables are region and year dummies, while in column (2) we display results from a richer specification where we include all control variables. We show the first-stage statistics for our instruments in rows 5 (partial R-squared) and 6 (*F*-statistics for joint significance of excluded instruments) of Table 7. The partial R-squared is high, suggesting that our instrument set explains about 90% of the variation in emigration rates. Likewise, the *F*-statistics for the significance of excluded instruments is 12.3 in the basic model (column (1)) and 10.2 in the model with all controls (column (2)).[23] The IV estimates are very close to the OLS estimates, indicating that emigration does have a positive effect on average wages in Poland (row 1), while having positive effects on wages of workers with a high (row 4) and, especially, an intermediate (row 3) level of education. The estimated effect for the group of low educated workers (row 2) is again negative, although imprecisely estimated. In Table B1 in the Appendix we also report IV results for the robustness checks discussed in section 2.3.In panel B, the instrument used is the deviation in each destination country's GDP per capita growth rate relative to the OECD mean, interacted with regional dummies and EU accession dummies. The first-stage statistics, reported in rows 5 and 6, indicate that these instruments are weaker than our preferred instruments, used in panel A. Nevertheless, the results from both instrument sets are very similar.

In panels C - G, we present IV estimates where we reduce the number of instruments. In panel C we use as instruments the wage growth in destination countries, but consider only

[23] According to Stock and Yogo's tabulations (2005), the critical value for the *F*-statistic when using 120 instruments is 11.31.

those region-country pairs for which wage growth is statistically significant at the 1% level of significance. This strategy reduces the number of instruments to 44, and leads to lower first-stage statistics, but the estimated coefficients are very close to those in panels A and B. In panel D and E we show estimates from a model where the instrumental variables are selected from the potential instruments set using backward (D) or forward selection (E)[24]. In both cases the first stage statistics increase considerably, although the number of instruments is reduced to 77 and 23, respectively. Estimates are again similar to our baseline results, although the magnitude increases slightly, especially in the case of forward selection. In panels F and G, we do not estimate the weights for the destination countries' wage growth, but compute them. For the results in panel F, we use the inverse of the distance between each region and the destination country to compute the weights; in panel G, we use the mean (over time) of the regional emigration share to each destination country. The partial R-squared (*F*-statistics) is lower in both cases, ranging from 0.13 (2.06) in panel F to 0.24 (4.43) in panel G. Nevertheless, the estimates in panel F and G are again similar to results in previous columns.

Overall, the IV results are remarkably stable despite the different instruments and weights used. While the weighting factors for the first set of instruments in columns A-E are estimated, the results of columns F and G rely on an IV strategy with pre-determined weighting factors. Despite a lower first stage, estimates are in line with those obtained using other estimation strategies, and confirm the pattern shown in the OLS results of a slight

[24] The backward selection is an iterative procedure where we start by running a first-stage regression including all regressors, and drop the least significant regressor at each subsequent re-estimation of the model. We iterate this procedure until all included regressors are at least statistically significant at the 10% level. In the forward selection we first fit a model with a constant only. We then add each potential regressor and select the one with the highest statistical significance. We iterate this procedure to add at each iteration one additional variable, as long as it is at least statistically significant at the 10% level.

overall increase in wages, and workers in the intermediate skills category experienced the largest negative supply shock, leading to the highest gains in wages.

5.3 Interpretation and comparison with previous studies.

How do our estimates compare to those of previous studies? As noted by Bratsberg et al. (2012) and Bratsberg and Raaum (2012), comparing our estimated coefficient β in equation (5) with those obtained from studies in other countries might be misleading because of cross-country differences in the size of the emigrant (or immigrant) population. For instance, while the average share of emigrants on the overall population is 16% for Mexico in 2000 (see Aydemir and Borjas 2007), it is only 2.3% in Poland in 2007, according to the PLFS. Thus, an increase in the share of emigrants by one percentage point is a far larger increase in the case of Poland (43%) than in the case of Mexico (6%). A more comparable measure of the responsiveness of wages to emigration is the *elasticity* of non-emigrant wages with respect to the size of the emigrant labour force, which is invariant to the size of the emigrant population. Further, this elasticity has the added advantage that it is unaffected by systematic undercounting, which could lead to an overestimate of the effects of emigration, as long as undercounting is proportional to the true number (see section 2.3). In our case, the elasticity of non-emigrant wages with respect to emigration is given by $\frac{\partial \ln w_{irt}}{\partial \ln E_{rt}} = \beta m_{rt}(1-m_{rt})$, where β corresponds to the estimated coefficient in the Tables above, and m_{rt} is the share of emigrants[25]. Evaluated at the sample mean emigrant share $\overline{m} = 1.2\%$, this elasticity lies between 0.01 (OLS results and baseline IV results) and 0.02 (our largest IV estimate), suggesting that a one percent increase in the number of emigrants increases wages by between 0.01 and 0.02 percent. These estimates compare, for instance, to an elasticity of

[25] $\beta = \frac{\partial \ln w_{irt}}{\partial m_{rt}} = \frac{\partial w_{irt} / w_{irt}}{\partial E_{rt} / E_{rt}} \frac{\partial E_{rt} / E_{rt}}{\partial m_{rt}} = \frac{\partial \ln w_{irt}}{\partial \ln E_{rt}} \frac{1}{m_{rt}(1-m_{rt})}$.

wages to immigration in the UK of 0.03, estimated by Dustmann et al. (2012). As regards the elasticity of wages by skill group, our estimates imply an elasticity between −0.03 and −0.02 for wages of low skilled workers, and elasticities for wages of intermediate and high skilled workers that lie between 0.02 and 0.04, and around 0.01, respectively.

We have no comparable estimates for the elasticity of wages to emigration. The estimates from the existing papers are obtained using the skill cell correlation approach, which only allow the computation of the direct partial wage elasticity of wages to emigration (i.e. the percentage change in wages of a skill group caused by a one percent increase in the number of emigrants in the same skill group, holding non-emigrant labour supply, aggregate supplies and capital constant). Nevertheless, evaluated at the sample mean emigrant/resident ratio of 10% and using the preferred coefficient estimate of 0.33, Mishra's (2007) results imply a partial elasticity of 0.033[26], while estimates of Aydemir and Borjas (2007) for Mexico over the years 1960-2000 imply an elasticity of 0.06 (obtained by evaluating their estimates of 0.8 at the mean ratio of emigrants to total population of 8.5%,), and Elsner's (2010) results imply a partial elasticity of 0.03 (evaluated at the estimated coefficient of 0.665 and at the mean share of 5%).

6. Discussion and Conclusions

We use the Polish Labour Force Survey to assess the effect that emigration over the 1998-2007 period —a time of large out-migration— had on the wages of Polish workers who did not emigrate. The PLFS is unique in two aspects: first, it asks households about household members who have migrated, which allows direct measurement of the migrant population,

[26] In Mishra's (2007) and Elsner's (2010) studies the regressor is $p_{irt} = \frac{E_{irt}}{R_{irt}}$; thus, the elasticity is equal to the estimated coefficient times the average share $\bar{p}$.

and second, it provides information about the emigrants' key characteristics, including age and educational level. We use this data to construct region- and skill-specific emigration rates.

Our basic results suggest that the large emigration experienced by Poland over the 1998–2007 period (when the emigrant share increased from 0.5 to 2.3%, and in some regions up to 5.6%) contributed to overall wage growth, particularly for workers in the intermediate skill group, which experienced the largest negative labour supply shock. Due to a possible correlation between region specific wage shocks and out-migration, OLS estimates that condition on region fixed effects are potentially downward biased, allowing us to interpret our results as lower bounds. To investigate this issue further, we implement an IV strategy based on labour market shocks to the various destination countries. Our IV results using different IV strategies are – overall – slightly larger than the fixed effect results and re-confirm a slight overall positive effect of emigration, with individuals in the intermediate-education group gaining most. These results are remarkably stable, and robust to various definitions of the wage variables, and checks on the potential mismeasurement of regional emigration rates.

Taken together, our findings suggest that emigration from Poland over the 1998–2007 period had a slightly positive (although not always precisely estimated) effect on the average wages of those who did not emigrate. Our results are thus in line with those that Aydemir and Borjas (2007) and Mishra (2007) find, with a different empirical strategy, for Mexican emigration. Within our theoretical framework (see Section 3), this finding implies that the supply of capital was, at least in the short run, not perfectly elastic. Moreover, the impact of migration on wages for the different skill groups seems to mirror the relative negative supply shocks experienced by these skill groups through emigration; that is, the emigrants were

drawn primarily from the medium and upper parts of the educational distribution in which positive wage effects are more pronounced. Not everyone gained, however: according to our point estimates, workers with a low education —the group that emigrated least and thus became relatively more abundant— experienced no wage gains and may even have experienced slight wage decreases, although estimates are insignificant for this skill group in most cases.

A Data Appendix

A.1 Sample Extraction

Poland is divided into 16 regions: Greater Poland (*województwo* wielkopolskie), Kuyavian-Pomeranian (*województwo kujawsko-pomorskie*), Lesser Poland (*województwo małopolskie*), Łódź Voivodeship (*województwo łódzkie*), Lower Silesian (*województwo dolnośląskie*), Lublin (*województwo lubelskie*), Lubusz (*województwo lubuskie*), Masovian (*województwo mazowieckie*), Opole (*województwo opolskie*), Podlaskie (*województwo podlaskie*), Pomeranian (*województwo pomorskie*), Silesian (*województwo śląskie*), Subcarpathian (*województwo podkarpackie*), *Świętokrzyskie* (*województwo świętokrzyskie*), Warmian-Masurian (*województwo warmińsko-mazurskie*) and West Pomeranian (*województwo zachodniopomorskie*). In our analysis, each region is considered to be a separate labour market. The average regional labour force (active and inactive) is about 1.7milion, with the largest region in both 1998 and 2007 being Masovian, the region of Warsaw, and the smallest region, Lubusz in 1998 and Opole in 2007. Figures A1 and A2 each shows a map of Poland with the 16 provinces marked, together with the yearly average wage increase and the yearly average change in the share of emigrants between 1998 and 2007, respectively.

For our analysis, we use data from 1998 to 2007 and restrict the sample to those between 15 and 65 years old. We eliminate wage observations below the 1st percentile and above the 99th percentile to eliminate outliers. To avoid selection problems resulting from changes in sample composition, we compute regional average wages by year and keep the sample used to compute these wages constant by dropping all individuals who are return migrants or emigrate within the next year. Mean wages by region are calculated using the population weights provided in the survey.

The variable *education* is defined by re-coding the original variable in the survey (which was classified into nine categories) into three categories: *low education group* = all individuals who have partially or fully completed primary school, or equivalently have 8 or less years of education ("*bez wykształcenia szkolnego*," "*niepełne podstawowe*" and "*podstawowe*"), *intermediate education group* = all those who have completed a vocational or general secondary education and have between 9 and 13 years of education ("*średnie zawodowe*," "*średnie ogólnokształcące*," "*gimnazjum*" and "*zasadnicze zawodowe*"), and *high education group* = all those who have a post-secondary or higher education or more than 13 years of schooling ("*wyższe*" and "*policealne*").

A.2 Weights: Estimation Strategy

Because the data set for emigrants reports no sampling weights, we estimate the weights for emigrants based on those we have for members of the labour force. From the information provided by the Polish Statistical Office, we know that the sampling units are households and the first stratum of the sampling procedure consists of regions. Weights are then defined on the basis of the response rate and certain other demographic variables (place of residence, gender and age). Based on this information, we estimate the following regression for each year *t*, quarter *q* and gender *s*:

$$weights_{itqs} = \sum_{r=1}^{R}\sum_{d=1}^{D}\sum_{y=1900}^{Y}\beta_{rdytqs}R_r * D_{itqs} * Y_{itqs} + u_{itqs} \text{ for } \forall t,q,s$$

where R_r are regional dummies, D_{itqs} are eight dummies for the size of the town in which the household resides, Y_{itqs} are year-of-birth dummies and u_{itqs} is an error term. After using

the above regression to estimate the weights for emigrants,[28] we use the weights obtained to compute all other emigrant information, such as total number of emigrants and share of emigrants in the total population.

A.3 Net and Gross Wages

The Polish LFS contains information about net monthly wages only. We reconstruct gross wages, applying Poland's three tax rates[29] to the three income brackets identified by the two tax base thresholds. We therefore apply the following formula:

$$grosswages_{it} = \begin{cases} \dfrac{netwages_{it} - TC_t}{1-\tau_t^L} & \text{if } netwages_{it} \le x_t^{L,N} \\ \dfrac{netwages_{it} - TC_t + x_t^{L,G}(\tau_t^L - \tau_t^M)}{1-\tau_t^M} & \text{if } x_t^{L,N} < netwages_{it} \le x_t^{H,N} \\ \dfrac{netwages_{it} - TC_t + x_t^{L,G}(\tau_t^L - \tau_t^M) + x_t^{H,G}(\tau_t^M - \tau_t^H)}{1-\tau_t^H} & \text{if } netwages_{it} > x_t^{H,N} \end{cases}$$

where $grosswages_{it}$ are the yearly gross wages for individual *i* at time *t*; $netwages_{it}$ are yearly net wages; TC_t are the tax credits for which individuals are eligible; and $x_t^{b.j}$ are the tax base thresholds, where *b* = L(low), H(high) and *j* = N(net), G(gross). We apply the net threshold to our data ($x_t^{L,N} = x_t^{L,G}(1-\tau_t^L)$; $x_t^{H,N} = x_t^{H,G}(1-\tau_t^M)$). The fiscal year in Poland corresponds to the calendar year. For each individual, we compute the yearly net wage (from the monthly net wages reported in the survey) and assign individuals to the respective tax base bracket.

[28] For emigrants, there is no information on the size of their town of residence before moving abroad. However, we do have information on the household the emigrant belonged to before emigration. We therefore assign the emigrant's town size based on this latter.

[29] Poland has an individual taxation system, but taxpayers can decide to pool their income with the income of other people in the family. Because we do not observe the actual behaviour of households, **w**e compute gross wages under the assumption that workers do not choose to pool earnings.

In 1999, a tax reform was introduced that required employees to pay their own social contributions (previously paid by employers). Hence, to make gross wages comparable across the years, we compute gross wages net of employees' social contributions. Finally, we divide the yearly gross wages by 12 in order to obtain monthly gross wages to use in the econometric analysis.

A.4 Missing Wages

Not only did the non-response rate to the PLFS wage question increase in later years, from 17% in 1998 to 32% in 2007, but the better educated are over-represented among non-responders, which may lead to under- or over-estimation of the effect of emigration, depending on the type of selection. Hence, to check the robustness of our results, we correct for differential non-response rates across different population groups and impute wages for employed individuals with missing wage information. Under the assumption that the probability of response to the wage question depends only on observable characteristics, this procedure allows us to recover measures of regional average log wages. Specifically, the imputation procedure works as follows. First, for each year, quarter and gender, we run separate regressions of log wages, controlling for age and education and their interaction, occupation, marital status, part-time work, whether the individual is a public sector employee, city size and region of residence.[30] We use the coefficients estimated in these regressions to predict wages for all employees in the sample for whom wage information is missing. We add an error term to the prediction, drawn from a normal distribution, with zero mean and

[30] We control for age using dummies for 10-year age brackets; for educational level with dummies for low, intermediate and high education; and for occupation using dummies for each 1-digit ISCO08 occupation group. The controls for city size are dummy variables for seven size categories, and those for region of residence are dummies for each *voivodship*.

heteroskedastic variance according to age, education and gender. We use these wages to compute regional means to be used in the econometric analysis.

A.5 Emigrant Share

The fact that we do not observe emigrants who live in single households before emigration implies that we may be under-estimating the number of Polish emigrants. However, as explained in Section 2.3, the percentage of single households in the age range at which most migrations take place is so low that their omission is unlikely to be a serious problem, especially as we demonstrate that our data on emigration to different countries closely resembles those constructed from data sources in the receiving countries. Nevertheless, as a robustness check, we also provide estimates in which we re-construct the share of single household emigrants using information on the share of single households among non-emigrants.

To do so, we first compute the share of individuals living in a single household in the resident population in year *t*, region *r*, age group *a* (using five 10-year age brackets) and education level *e* (using three education levels), α_{raet}. Under the assumption that the share of single households, conditional on observable characteristics, is the same among residents and emigrants, we then re-scale the number of observed emigrants in each year-region-age-education cell E^{*}_{raet} by $1/1-\alpha_{raet}$ to obtain an estimate of the actual number of emigrants in that cell, $E_{raet} = E^{*}_{raet}/1-\alpha_{raet}$. We then sum up the adjusted numbers of emigrants by region and year and compute the shares to be used in the regression. Adjusting for under-counting of single households, the share of emigrants in the total working age population is 0.7% in 1998 and 2.8% in 2007, which compares with 0.5% and 2.3%, respectively, without the adjustment.

B. IV Construction

In this Appendix we provide details on our choice of "pull factors" for the construction of our main instrumental variables.

In our preferred specification, we define z_t^j as the annual growth rate of real wages below the 40th percentile in country *j* (U.S., UK or Germany) and wages in the construction and manufacturing sector for Ireland, expressed in zloty. We choose the growth rate of mean wages below the 40th percentile to measure the attractiveness of destination countries for Polish emigrants because these fall into the lower part of the wage distribution in host countries, especially in the first years after migration. This fact is demonstrated in Figure B1, which uses, respectively, IABS, CPS and UK LFS data to plot the position of Polish immigrants in the wage distribution for Germany, the U.S. and the UK: for all three countries, Poles are in the lower part of the distribution for natives. For Ireland, for which we have no micro-data but only aggregate data by industry, the 2006 Irish Census indicates that over half of Polish male immigrants are working in construction and manufacturing (Irish Central Statistical Office 2008). Moreover, we calculate wages in zloty, which accounts for fluctuations in the exchange rate of the U.S. dollar, British pound and the euro *vis-a vis* the Polish currency. This latter is important because a large portion of the earnings is likely to be spent in Poland either through re-allocation to families in the form of remittances or through the temporariness of migration, which means that savings are later spent at home (see e.g. Dustmann 1997). As Table B2 shows, such exchange rate fluctuations were sizeable during the years under consideration and contributed substantially to changes in the earnings differential of Polish workers in Poland and abroad in terms of their purchasing power in Poland.

Table 1: Number of Poles Abroad

	Stock	Change	Flow	Population share
	in thousands	%	in thousands	%
1994	192.472			0.79
1995	185.389	-3.7	-7.083	0.74

Source: Polish LFS

Note: In column 1 we report the share of all working age (15-65) emigrants and the share of recent emigrants (those who emigrated within the last year) in the total working age population for Germany, the U.K., the U.S., Ireland and Europe (EU27) in 1998 and 2007. In columns 2-4 we report the distribution of education for each group in 1998 and 2007 and in the last column we report the average age of each group in 1998 and 2007.

Table 5: Descriptive Statistics

Variables	Mean	Std. Dev.	Variables	Mean	Std. Dev.
Non-Emigrants			Emigrants		
			share of emigrants	1.2%	1.0%
% female	51%	1%	% female	40%	11%
age	38.3	0.5	age	33.0	2.4
intermediate/low educated	3.0	1.1	intermediate/low educated	12.8	10.2
high/low educated	0.7	0.3	high/low educated	3.0	3.3
Net Wages			Net Wages		
log average	6.99	0.06	log average	6.95	0.34
log average low ed.	6.74	0.09	log average low ed.	6.40	1.72
log average intermediate ed	6.94	0.59	log average intermediate ed.	6.55	1.45
log average high ed.	7.23	0.08	log average high ed.	6.62	1.39

Source: Polish LFS

Note: We report pooled means and standard deviations for all regions and years (1998 to 2007). Entries are the percentage of females, the age, share of intermediate and high educated over low educated, real net average wage and real net wages by education group for non-emigrants. For emigrants we also report the share of emigrants over the total working age population. For emigrants, wages are wages in poland before emigration. Real wages are at 2008 prices. Non-emigrants and emigrants in the working age population (15-65).

Table 6: Effects of Emigration on Log Mean Wages, OLS

obs	160	160	160	160	160	160	160	160

*Note: Entries are estimated regression coefficients of the regional ratio of emigrants over the total population on regional average log net wages and on average log wages by education groups for years 1998-2007. In each panel we use a different measure of average, low, intermediate and high wages. In Panel A we use net monthly wages. In Panel B we use gross wages. In Panel C we impute wages for employed individuals with missing wage information. In Panel D we adjust the share of emigrants by the share of single households in the population. All regressions include region fixed effects. "Other controls": log regional population, mean regional age and gender, share of intermediate educated and high over low educated. Newey-West standard errors using 1 lag are reported in parenthesis. * indicates signifcance at 10%, ** indicates significance at 5%, *** indicates significance at 1% level.*

*Note: Entries are estimated regression coefficients using different instrumental variables for the regional share of emigrants over the total population in regressions of average regional log net wages on the regional emigrant shares and region and year dummies for years 1998-2007. In Panel A the IV are the annual growth rate of real wages below the 40th percentile in country j (USA, UK and Germany) and wages in the construction and manufacturing sector for Ireland, expressed in zloty interacted with regional dummies. In Panel B we use the GDP growth deviation and we interact regional dummies with the deviation of the GDP growth of destination country j from the OECD mean GDP growth (in US constant dollars). In Panel C we select instruments which are significant at 1% and run the first stage regression using the selected instruments only. In panels D and E, we select the variables using a backward (D) and forward (E) selection. In Panel F, we interact the mean wage growth at the 40th percentile by the inverse of the distance of the regional capital from the capital of the country of destination. In Panel G, we interact the mean regional share of emigrant in destination country j with the wage growth in the same destination country j. "Other controls": log regional population, mean regional age and gender, share of intermediate educated and high over low educated. Newey-West standard errors using 1 lag are reported in parenthesis. * indicates signifcance at 10%, ** indicates significance at 5%, *** indicates significance at 1% level.*

Table A1: Average annual number of observations by region

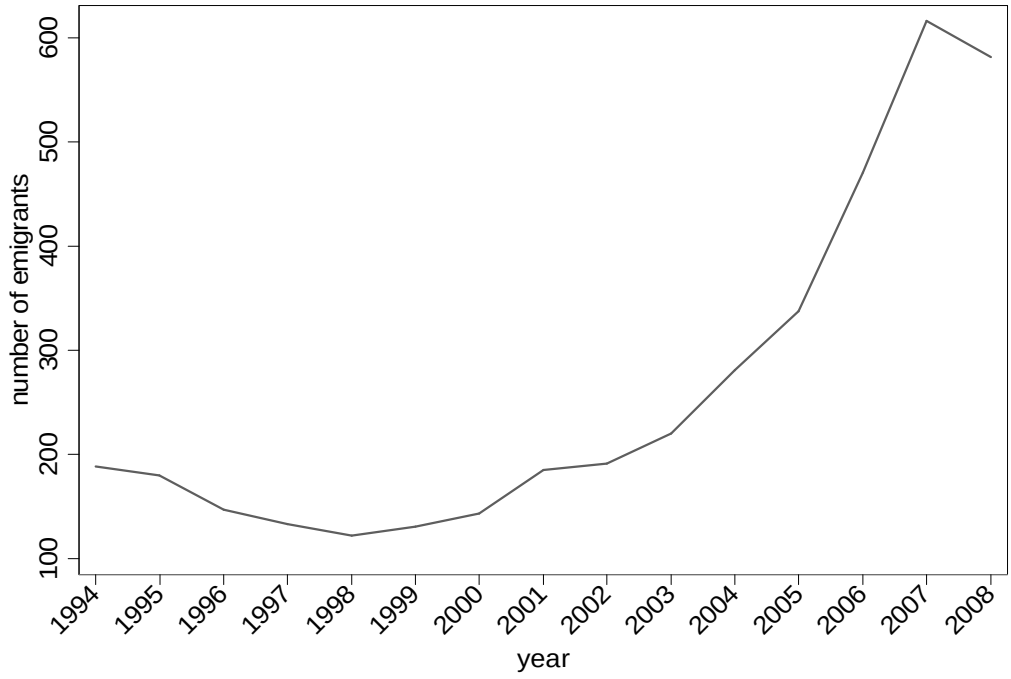
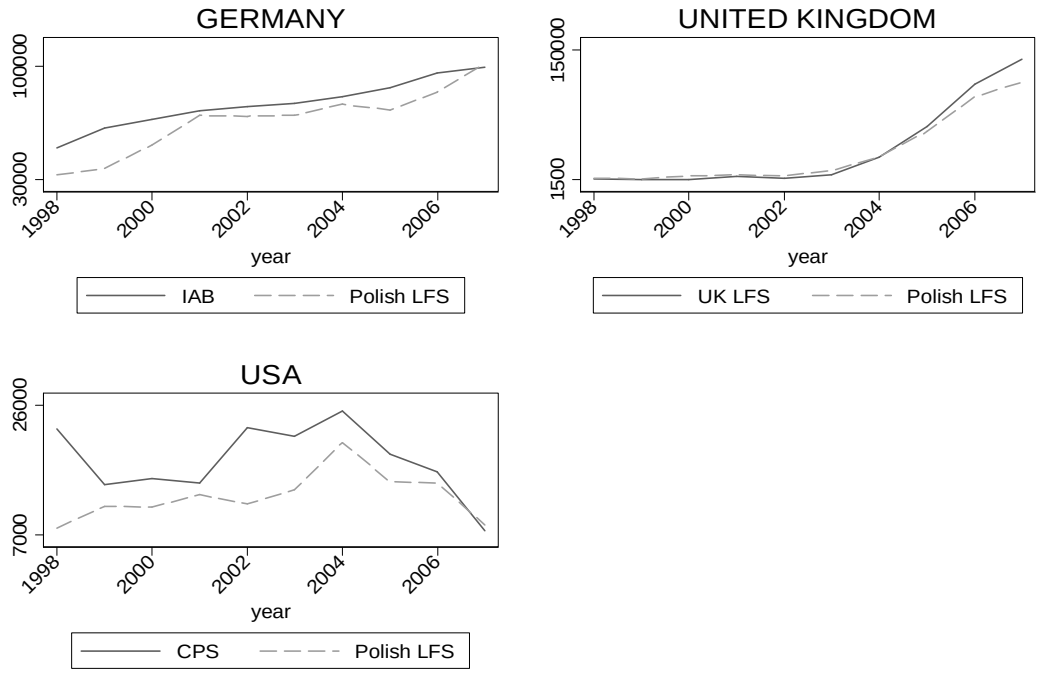
[2] Exchanges rates are collected from the IMF publication "International Financial Statistics" and refer to IMF series "rf": year average national currency per U.S. dollars.

Figure 1: Total Number of Emigrants, from 1994 to 2008, in thousands



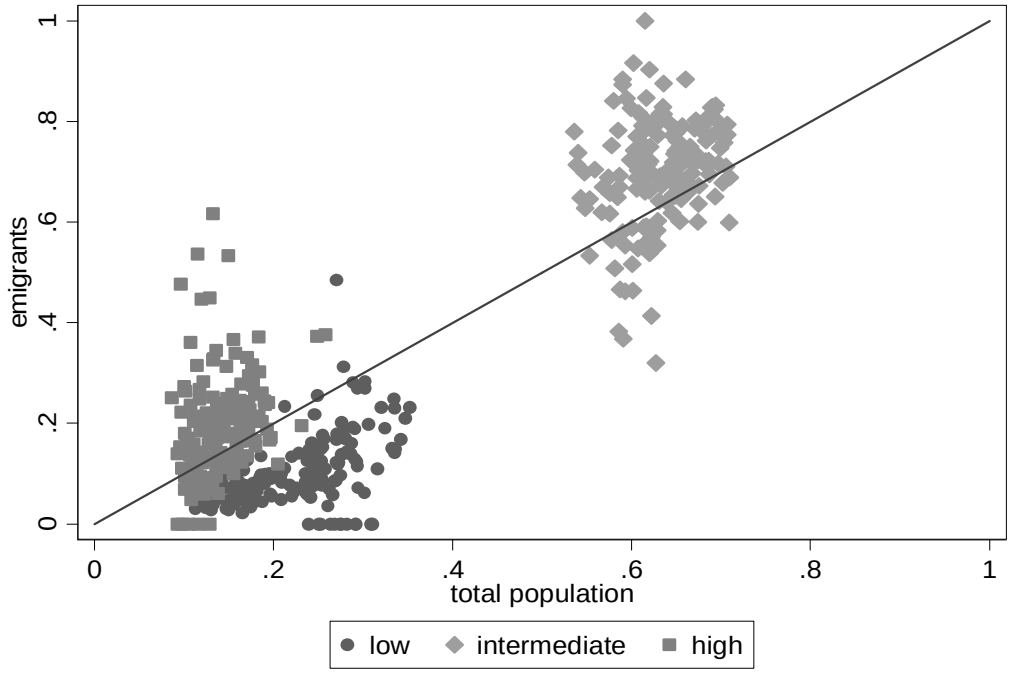
Source: Polish LFS
Note: Total stock of Poles residing abroad. Average of the quarters over each year

Figure 2: Number of Poles abroad from the Polish LFS and other datasets, a comparis



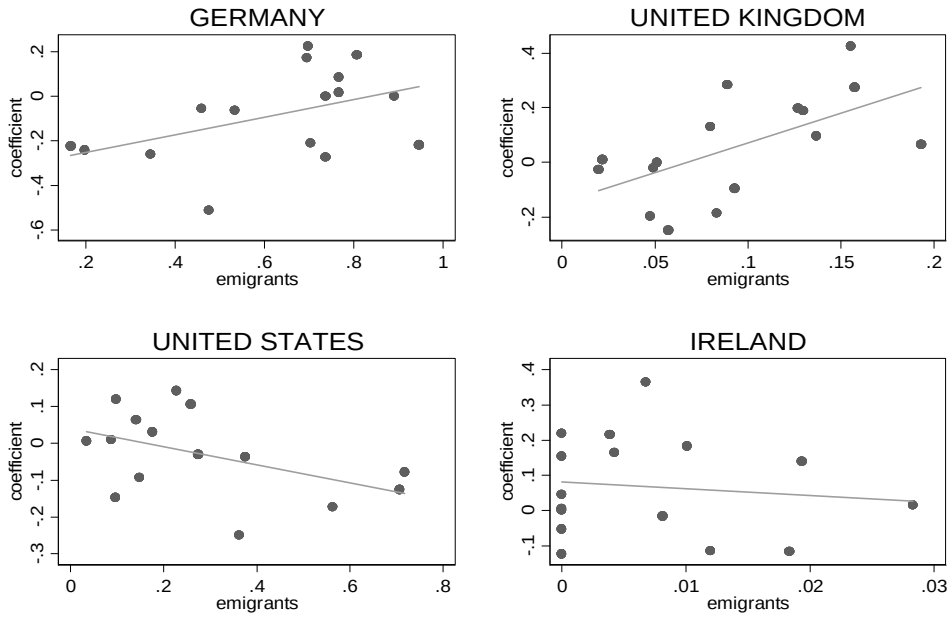
Note: For each destination country, we report the stock of Polish immigrants between 1998 and 2007. For the UK and USA we have information on the year of arrival in the country, so that we can report just recent immigrants (in the country for one year or less). For Germany we report all Polish immigrants. We smooth estimates in the USA by taking a moving average over a three year period (t-1, t, t+1), in each year.

Figure 3: Emigrants and total population: shares in each education group



Source: Polish LFS
Note: The figure plots for each region and year the proportion of working age (15-65) emigrants in each education group versus the proportion of total working age population in the same
Years 1998-2007.

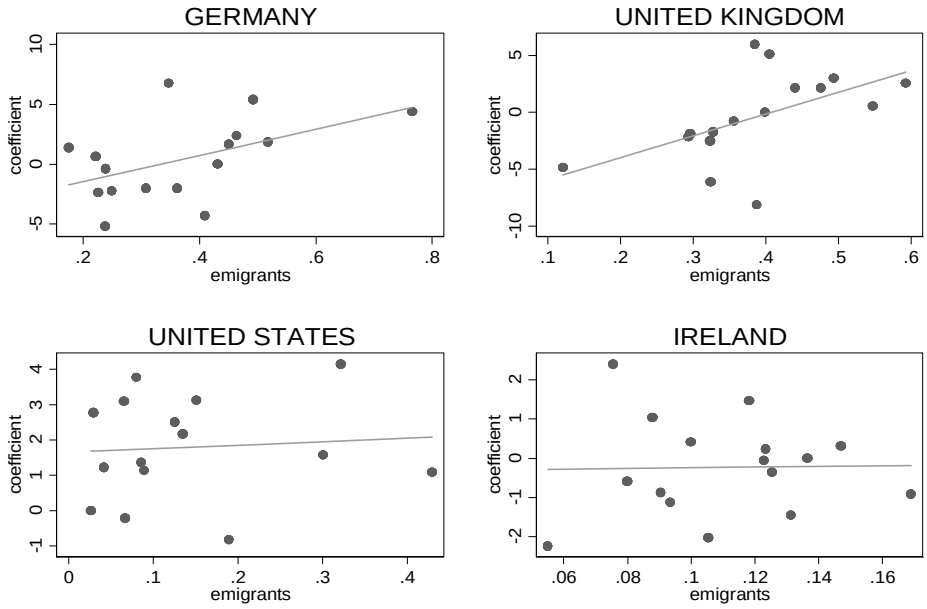
Figure 4: Pre-2004 first stage coefficients and emigrant share by destination country and region



Source: Polish LFS

Note: In each panel of the graph we plot the first stage coefficient pre-2004 for each region versus the mean share of emigrants in the same region. Each coefficient measures the effect of a wage shock in the destination country on emigration from each Polish region. The measure of emigrants we use is the average percentage of emigrants in the region to the destination country between 1998 and 2004 (excluded).

Figure 5: Post-2004 first stage coefficients and emigrant share by destination country and region



Source: Polish LFS

Note: In each panel of the graph we plot the first stage coefficient post-2004 for each region versus the mean share of emigrants in the same region. Each coefficient measures the effect of a wage shock in the destination country on emigration from each Polish region. The measure of emigrants we use is the average percentage of emigrants in the region to the destination country between 2004 (included) and 2007.

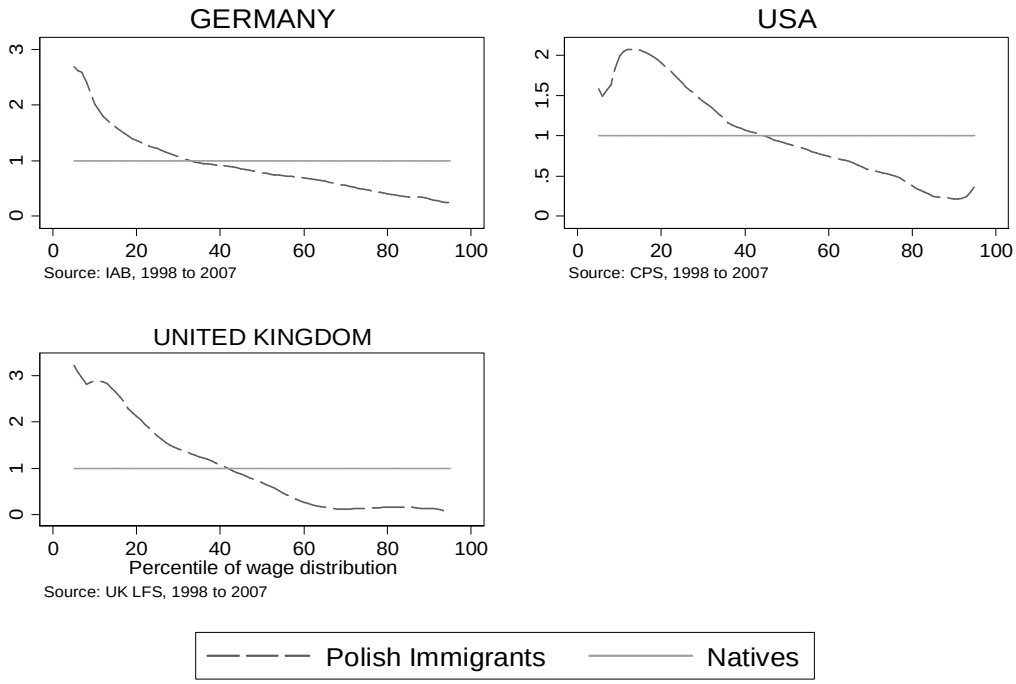
Figure A1: Yearly Average Increase in Wages, 1998-2007

Source: Polish LFS
Note: Annual average increase in real wages between 1998 and 2007

Figure A2: Yearly Average Increase in the Share of Emigrants (% points), 1998-2007

Source: Polish LFS
Note: Annual average increase in the share of emigrants (in percentage points) between 1998 and 2007.

Figure B1: Polish emigrants in the destination countries' wage distribution



Note: The graphs report the relative distribution of Polish immigrant wages in the wage distribution of natives in Germany, the U.S. and the U.K., for years 1998-2007 pooled, using data from the destination countries. For the U.K. and the U.S. the figures refer to recent immigrants (less than two years in the country), for Germany the figure refers to all Polish emigrants.
